Abstract

Peripheral airway smooth muscle (ASM) mass is increased in severe equine asthma, but no information exists on the timing of such a structural alteration during the development of the disease. In order to elucidate the mechanisms driving ASM remodeling during disease, anatomical ASM development has to be evaluated first. This study investigated the morphometric alterations sustained by peripheral ASM during aging in healthy horses. The thickness of the peripheral ASM layer was found to be constant in horses of all ages, but it occupies a greater proportion of the inner wall area in younger than in older horses. This finding suggests that equine airways physiologically experience a decrease in the relative abundance of ASM with age. Failure to do so may play a role in equine asthma development.

Keywords: Airway smooth muscle; Development; Foal; Lung; Peripheral airways.

Severe equine asthma, also known as recurrent airway obstruction (RAO) or heaves, is a chronic obstructive disease affecting adult horses exposed to environmental antigens as found in hay and straw dust. Following exposure, affected horses develop pulmonary inflammation associated with a severe bronchoconstrictive response caused by exaggerated airway smooth muscle (ASM) contraction (Leclere et al., 2011b). Several studies have shown that the ASM mass is increased in severely asthmatic horses, particularly in the peripheral airways, thereby contributing to airflow obstruction (Herszberg et al., 2006; Leclere et al., 2011a; Bullone et al., 2015).

Despite the central role of the increased ASM in severe equine asthma, no information is available concerning the timing of these structural alterations during disease development. Moreover, it remains unclear whether this remodeling results from an abnormal growth or from a failure of involution/regression mechanisms normally occurring during airway development in healthy subjects. To clarify these issues, an accurate description of the postnatal ontogenesis of ASM in healthy horses is required. The present study aims to investigate the anatomical alterations sustained by the peripheral ASM with ageing in a cohort of healthy horses.

Peripheral lung tissues harvested post-mortem from healthy horses were obtained from the Equine Respiratory Tissue Bank[1] or from the histological archives of the authors' institution. Horses were defined as healthy based on history (absence of respiratory signs), blood work results (when available), and histopathological findings. Histological sections of 5 µm thickness were stained with hematoxylin-eosin-phloxyn-saffron (HEPS). Five airways per horse with a major to minor axis ratio <1.5, with an intact epithelium, and with smooth muscle surrounding ≥70% of their circumference were studied. The ASM area, the outer border of ASM, and the internal perimeter length (Pi) were measured in cross-sectionally cut peripheral airways using Image J (NIH). ASM mass was expressed as ASM/Pi (corrected by the internal perimeter to account for variation in airway size) and as ASM% (percentage of the inner airway wall occupied by ASM, where the inner

[1] See: www.ertb.ca (accessed 04/05/2017).

airway wall area was calculated as the difference between the area enclosed by the external border of ASM and the airway lumen area enclosed by Pi; Fig. 1). Measurements were performed by one investigator blinded to the subject identity. For statistical analysis, horses were divided in six age groups (0-6 months, 6-12 months, 1-4 years, 5-10 years, 11-20 years, and >20 years). Further methodological details are provided online (see Appendix A: Supplementary material).

Tissues harvested from 51 healthy horses ranging from 1 day to 32 years of age were studied. Table 1 details their age, sex distribution, and average airway size. ASM/Pi, an indirect measure of ASM thickness, did not change with age in the horses studied (P=0.3; Fig. 2A). However, ASM/Pi significantly increased with increasing airway size when airways of all groups were analysed together (r^2=0.11, P<0.0001; Fig. 2B). ASM%, which represents the percentage of the inner bronchial area occupied by ASM bundles, decreased significantly with ageing (P=0.02; Fig. 3A). There was no significant difference in the mean ASM% of foals in the different age groups (see Appendix A: Supplementary material). With the exception of horses aged 11-20 years, in which ASM% decreased with increasing airway size (P=0.04), ASM% was not affected by airway size (P>0.1; Fig. 3B).

The increased ASM mass observed in the peripheral airways of severely asthmatic horses plays a central role in disease development and clinical presentation, as shown by a recent study in which a significant association was found between the degree of peripheral ASM remodeling and disease severity expressed in terms of lung function (Bullone, 2016). As both genetic and environmental factors contribute to severe equine asthma development (Leclere et al., 2011b), the structural alterations of peripheral airways contributing to airflow obstruction could precede the appearance of clinical signs and occur earlier in a horse's life. Interestingly, the mild form of equine asthma known as inflammatory airway disease (IAD), which is common among young athletic horses and is considered a risk factor for the development of the severe form of the disease

(Bosshard and Gerber, 2014), is characterised by airway hyperreactivity, i.e. an exaggerated bronchoconstrictive response. To elucidate the mechanisms driving ASM remodeling in equine asthma, normal smooth muscle development needs to be evaluated first. Our study provides the first data on peripheral ASM postnatal ontogenesis in the equine species. These results show that peripheral airways of similar size have an ASM layer characterised by a constant thickness. However, a higher proportion of the inner bronchial area is occupied by ASM in the fast-growing foals compared to what is observed in adult horses. Such age-related decrease of ASM% can be caused by an increased epithelial or lamina propria area, or both. Previous studies have reported an unchanged peripheral ASM thickness in children vs. men (Hislop and Haworth, 1989), which is in agreement with our results. An age-related decrease in peripheral ASM bundle size (corrected by airway dimensions) was reported in rhesus monkeys which, if occurring in man as well, might explain the increased airway hyperreactivity observed during childhood (Tran et al., 2004). In fact, in airways of similar size, the ability of the ASM to contract and induce bronchospasm is proportional to its mass. Increased ASM% has also been reported in young vs. old rabbits (Ramchandani et al., 2000), while the same was not observed in swine (Murphy et al., 1991). However, the latter study was limited to the large conducting airways. As a limitation of the current study, our data are limited to small peripheral airways, and therefore, the observed effects of airway size may not reflect what occurs when the entire bronchial tree is considered.

In conclusion, our study provides fundamental information on the anatomical development of ASM mass in healthy horses and paves the way for detecting asthma-related alterations in this process. The increased ASM% observed in young horses deserves attention as it could be associated with increased hyperresponsiveness and may be implicated in the pathogenesis of mild forms of equine asthma.
